### ABSTRACT

A unique set of geochemical pore-water data, characterizing the sulfate reduction and uppermost methanogenic zones, has been collected at the Blake Ridge (offshore southeastern North America) from Ocean Drilling Program (ODP) Leg 164 cores and piston cores. The  $\delta^{13}\text{C}$  values of dissolved  $\text{CO}_2$  ( $\Sigma\text{CO}_2$ ) are as  $^{13}\text{C}$ -depleted as  $-37.7\%$  PDB (Site 995) at the sulfate-methane interface, reflecting a substantial contribution of isotopically light carbon from methane. Although the geochemical system is complex and difficult to fully quantify, we use two methods to constrain and illustrate the intensity of anaerobic methane oxidation in Blake Ridge sediments. An estimate using a two-component mixing model suggests that  $\sim 24\%$  of the carbon residing in the  $\Sigma\text{CO}_2$  pool is derived from biogenic methane. Independent diagenetic modeling of a methane concentration profile (Site 995) indicates that peak methane oxidation rates approach  $0.005 \mu\text{mol cm}^{-3} \text{ yr}^{-1}$ , and that anaerobic methane oxidation is responsible for consuming  $\sim 35\%$  of the total sulfate flux into the sediments. Thus, anaerobic methane oxidation is a significant biogeochemical sink for sulfate, and must affect interstitial sulfate concentrations and sulfate gradients.

Such high proportions of sulfate depletion because of anaerobic methane oxidation are largely undocumented in continental rise sediments with overlying oxic bottom waters. We infer that the additional amount of sulfate depleted through anaerobic methane oxidation, fueled by methane flux from below, causes steeper sulfate gradients above methane-rich sediments. Similar pore water chemistries should occur at other methane-rich, continental-rise settings associated with gas hydrates.

### INTRODUCTION

Sulfate reduction refers to microbially mediated diagenetic processes that deplete sulfate within interstitial pore waters. In anoxic marine sediments, sulfate reduction is generally the most important remineralization process (e.g., Reeburgh, 1983), with the net reaction adding dissolved carbon dioxide ( $\Sigma\text{CO}_2$ , or dissolved inorganic carbon, DIC) and sulfide to pore waters. Sulfate depletion typically occurs when microbes utilize interstitial sulfate that is ultimately derived from overlying seawater, to oxidize sedimentary organic matter (SOM) in the net reaction:

which also releases ammonium and phosphate to pore waters as net by-products of SOM degradation (Richards, 1965). An additional sink for sulfate occurs near the base of the sulfate reduction zone, or sulfate-methane interface (SMI), in a net process called anaerobic methane oxidation (AMO):

(Reeburgh, 1976). Although sulfate and methane are apparently co-consumed in the net reaction, the pathway for this process is controversial (e.g., Hoehler et al., 1994).

In most marine sediments, oxidation of SOM (Eq. 1) is the predominant reaction that controls interstitial sulfate concentrations and gradients. However, in methane-charged sediments like those overlying gas hydrate deposits, AMO may become an important process that affects interstitial sulfate concentration gradients. Borowski et al. (1996) linked interstitial sulfate depletion in Carolina Rise and Blake Ridge (CR-BR) (offshore southeastern United States) sediments to upward methane flux and underlying methane inventory. In such methane-rich settings, AMO potentially consumes a significant portion of the interstitial sulfate pool, depleting sulfate more rapidly than oxidation of SOM alone. The underlying methane concentrations regulate the upward methane flux (usually through diffusion) and thus also control the rate of AMO. Steep sulfate gradients (and perhaps their linearity) and shallow depths to the sulfate-methane interface are a consequence of the increased influence of AMO within these continental rise sediments (Borowski, 1998).

We analyze geochemical evidence from Ocean Drilling Program (ODP) drilling on the Blake Ridge (Leg 164) to assess the importance of AMO as a mechanism influencing sulfate depletion. The data presented here are unique because of high-resolution sampling ( $\sim 1$ - to  $1.5$ -m intervals) through the upper methanogenic zone and entire sulfate reduction zone. The results substantiate inferences drawn from measurement of sulfate gradients in sediments collected previously by piston coring (Borowski et al., 1996, 1997; Borowski, 1998). Sulfate gradients are steep (and linear) within these methane-rich, continental-rise sediments, and supporting concentration and isotopic data used in simple mixing and diagenetic models demonstrate that AMO is a significant sink for sulfate. We infer that such a magnified role for AMO influences the magnitude and shapes of sulfate gradients in other marine, methane-rich settings associated with gas hydrates.

102, 103, and 104; Hollister, Ewing, et al., 1972), from DSDP Site 533 (Leg 76, Sheridan, Gradstein, et al., 1983), and from 87 piston cores taken over the Blake Ridge and Carolina Rise (Borowski et al., 1996, 1997) (Fig. 1).

Three sites drilled on Leg 11 form a transverse transect on the Blake Ridge (Fig. 1) over prominent bottom-simulating reflectors (BSRs). The BSRs suggest the presence of gas hydrates in the subsurface (Lancelot and Ewing, 1972; Shipley et al., 1979). Moreover, although interstitial data from this leg are sparse, chloride data show strong downward freshening (Sayles et al., 1972; Presley and Kaplan, 1972), also suggesting gas hydrates are contained within the sediments (Hesse and Harrison, 1981). Sulfate data indicate that shallow sulfate-methane interfaces occur between 6 and 45 mbsf.

Site 533 was also drilled over a strong BSR, and interstitial chemical data show downward-freshening chloride profiles and  $^{18}\text{O}$ -enrichments in pore waters (Jenden and Gieskes, 1983), indicating the presence of gas hydrates (Hesse and Harrison, 1981; Davidson et al., 1983). Sulfate data are insufficient to fully document the shape of the concentration profile, but sulfate is depleted between 9.8 and 14.4 mbsf (Claypool and Threlkeld, 1983). Methane and  $\text{CO}_2$  data were used to identify large  $^{13}\text{C}$  depletions of carbon in the dissolved  $\text{CO}_2$  ( $\delta^{13}\text{C}_{\Sigma\text{CO}_2} = -31.4\%$  at 14.4 mbsf; Claypool and Threlkeld, 1983) and methane ( $\delta^{13}\text{C}_{\text{CH}_4} = -91.3\%$  at 33.9 mbsf; Galimov and Kvenvolden, 1983) pools, but did not provide isotopic data through the SMI.

Sulfate gradients at nondiapir sites over the CR-BR gas hydrate field are linear and vary by sixteenfold over the area as shown by piston coring (see fig. 1 in Borowski et al., 1996; fig. 2.1 in Borowski, 1998). However, the sulfate-methane interface was penetrated by only one piston core (PC 11-8; Fig. 1), where the depth to the sulfate-methane interface is 10.3 mbsf (Fig. 2C), the shallowest SMI depth observed or inferred in the CR-BR area.

The inference that linear sulfate gradients indicate a focused sink for pore-water sulfate over the breadth of the Blake Ridge, as well as the occurrence of large  $^{13}\text{C}$  depletions in interstitial  $\Sigma\text{CO}_2$  and methane (Borowski et al., 1996, 1997), prompted us to sample Leg 164 sediments in an unusually detailed manner. Our objective was to gather additional supportive evidence documenting the occurrence of AMO, and to quantify its role in sulfate depletion in methane-rich, gas-hydrate settings.

## METHODS

Pore-water data from the Blake Ridge (Fig. 1) were gathered from sediments collected by both ODP operations on Leg 164 and piston coring.

### Sediment Sampling and Geochemical Measurements

Procedures for collecting and processing piston core sediments and their pore waters are described in Borowski (1998). Sediments collected from ODP cores were sampled and processed using standard ODP methods, except that pore-water samples were taken more frequently at every  $\sim 1.5$  m (1 sample per section, or 6 samples per core) (e.g., Fig. 3). Pore waters were extracted from sediments using a hydraulic sediment press (Manheim, 1966) and collected in airtight syringes (Manheim and Sayles, 1974). Sulfate concentration was determined by ion chromatography, and alkalinity was measured by titration (Gieskes et al., 1991). Total carbon dioxide ( $\Sigma\text{CO}_2$ ) was separated and measured onshore using cryogenic and manometric techniques (Craig, 1953) from pore-water aliquots stored immediately after squeezing in flame-sealed, airtight ampoules. Methane concentrations within piston core and Site 994 sediments were measured on shipboard using headspace methods (Martens and Klump, 1980; Kvenvolden and McDonald, 1985; Borowski et al., 1997) and nor-

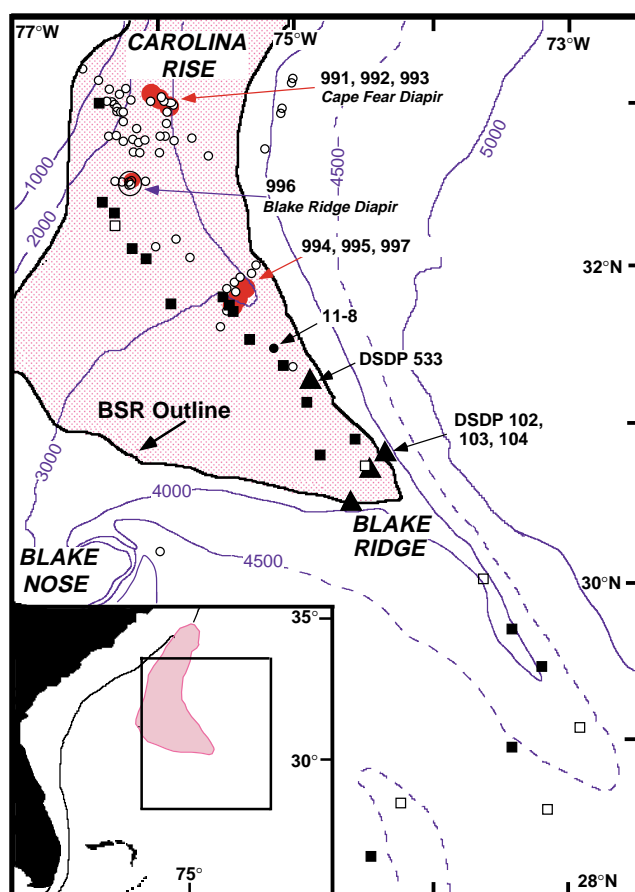

Figure 1. Map showing the location of ODP Leg 164 sites (large, solid circles), DSDP sites (solid triangles), and piston cores (small circles and squares; Borowski et al., 1997). Bathymetric contours are in meters after Uchupi (1968). The outline of bottom-simulating reflectors (BSRs; shaded) is based on the mapping of Dillon and Paull (1983).

malized to pore space volume (Paull, Matsumoto, Wallace, et al., 1996). Methane concentrations from Site 995 pore waters were measured from subcores transported to an onshore laboratory, and normalized to pore space volume (Hoehler et al., Chap. 8, this volume).

$\Sigma\text{CO}_2$  was separated and purified using cryogenic techniques (e.g., Craig, 1953). Carbon-isotopic-composition measurements of  $\Sigma\text{CO}_2$  are reported relative to the Pee Dee belemnite (PDB) standard, and were made using a Delta E mass spectrometer at North Carolina State University (NCSU). The cumulative (vacuum line and mass spectrometer) accuracy and precision of isotopic measurements are  $\pm 0.2\%$  and  $\pm 0.06\%$  (Neal Blair, pers. comm., 1996).

Sulfur isotopic measurements of interstitial sulfate were made at Geochron Laboratories (Cambridge, MA). Sulfate within pore waters was precipitated as barium sulfate, thermally decomposed to  $\text{SO}_3$ , and reduced to  $\text{SO}_2$  gas for isotopic measurement (Holt and Engelke-meir, 1970). Measurements were made using a VG Micromass mass spectrometer (Model 903), and are reported relative to the Canyon Diablo Troilite (CDT) standard. Measurement precision is  $\pm 0.1\%$  and cumulative accuracy is  $\pm 0.3\%$  (Marshall Otter, pers. comm., 1997).

### Diagenetic Model

Variations in the concentration of interstitial constituents relative to time and depth can be described by equations relating the mass-

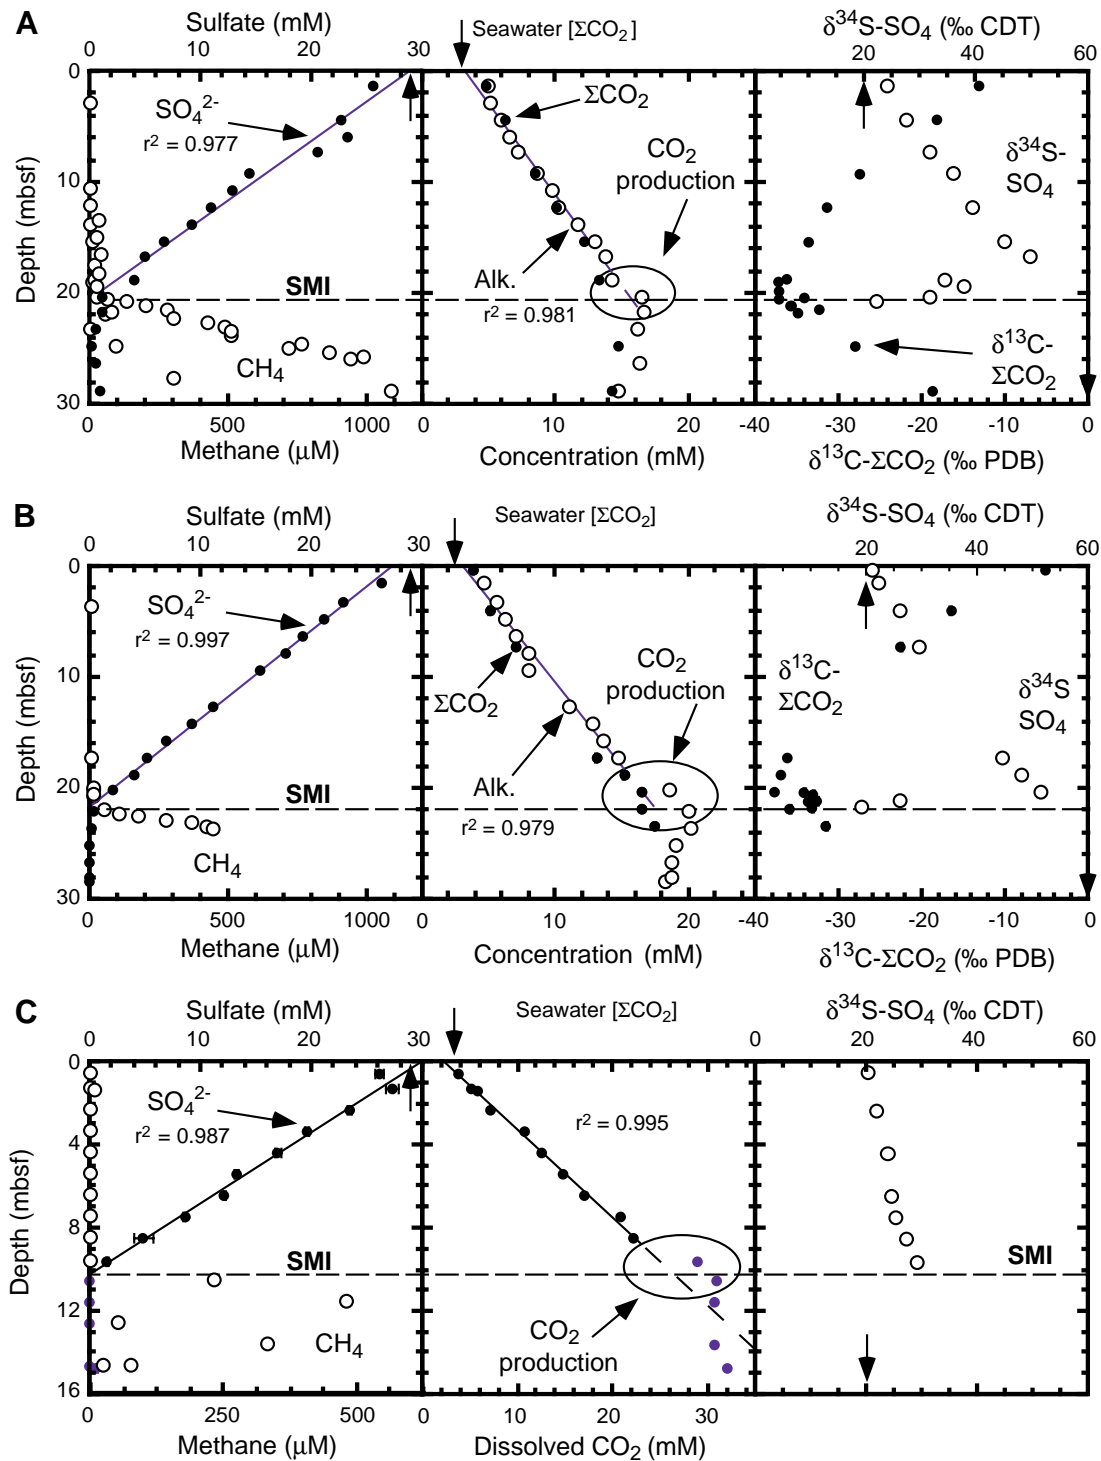

Figure 2. Pore-water concentration profiles for sulfate ( $\text{SO}_4^{2-}$ ) and methane ( $\text{CH}_4$ ); total dissolved carbon dioxide ( $\Sigma\text{CO}_2$ ) and alkalinity (Alk.); and isotopic composition profiles of  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  and  $\delta^{34}\text{S}_{\text{SO}_4}$  for (A) Site 994, (B) Site 995, and (C) piston core (PC) 11-8. Concentration is expressed in millimolar (mM) units for sulfate,  $\Sigma\text{CO}_2$ , and alkalinity; methane concentration is expressed in micromolar ( $\mu\text{M}$ ) units. Measurement uncertainties are shown with error bars, but are generally smaller than symbol size. Carbon isotopic composition is relative to the Peedee belemnite (PDB) standard; sulfur isotopic compositions are relative to Canyon Diablo Troilite (CDT). Representative seawater values for concentration and isotopic composition are shown with solid arrows pointing to the x-axes. The sulfate-methane interface (SMI) is shown by the horizontal dashed lines. Sulfate gradients are linear (note correlation coefficients,  $r^2$ , from least-square regression) within >95% probability ( $t$  test; Young, 1962).

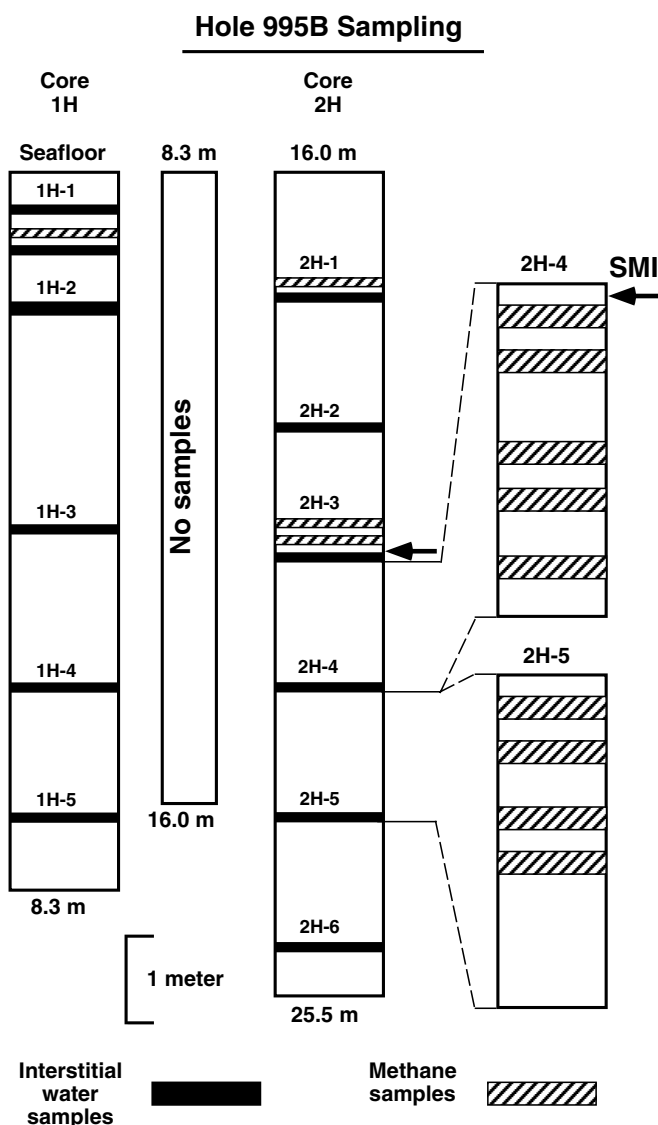

Figure 3. Schematic diagram showing the high-resolution sampling of sediments in Hole 995B. Cores 164-995B-1H and 2H sampled the sulfate-reduction and uppermost methanogenic zones. Core depths in meters (m) are cumulative; note that sediments from 8.3 to 16 m were not sampled. Also note that two sections of Core 164-995B-2H (Sections 2H-4 and 5) were sampled further to measure methane concentrations (Table 3; Hoehler et al., Chap. 8, this volume). The sulfate-methane interface (SMI) at Site 995 is at 20.5 meters below seafloor (mbsf). Samples 4.5 m above and 5 m below the SMI were taken in the same core (Core 164-995B-2H), so that the samples accurately record depths (with concentration and isotopic data) relative to the SMI.

transport processes of diffusion, advection (burial and compaction) to consumption and production reactions (e.g., Berner, 1980). The general diagenetic equation used here is

$$\frac{\partial C}{\partial t} = \phi^2 D_0 \frac{\partial^2 C}{\partial x^2} + \left( 3\phi D_0 \frac{\partial \phi}{\partial x} - \frac{\omega_{\infty} \phi_{\infty}}{\phi_x} \right) \frac{\partial C}{\partial x} + R_x = 0, \quad (3)$$

where  $C$  is concentration,  $t$  is time,  $\phi$  is porosity,  $D_0$  is the free-solution diffusion coefficient,  $x$  is depth below the sediment-water interface,  $\omega$  is sedimentation or burial rate, and  $R$  is reaction rate (Berner, 1964, 1977). The subscript ( $\infty$ ) refers to the depth where  $\partial\phi/\partial x$  approaches zero. This form of the diagenetic equation was initially applied to anoxic, methane-oxidizing sediments by Murray et al. (1978).

The model explicitly assumes that: (1) steady state conditions occur (i.e.,  $\partial C/\partial t = 0$ ); (2) vertical concentration gradients are much greater in magnitude than horizontal gradients; (3) sediment burial, compaction, and molecular diffusion are the only mass-transport processes (no fluid advection, bioirrigation, or gas ebullition occurs); (4) the free-solution diffusion coefficient and sediment density are constant with depth; and (5) the diffusion coefficient within sediment ( $D_s$ ) is related to free-solution diffusion coefficient by the expression,  $D_s = \phi^2 D_0$  (Ullman and Aller, 1982).

An inverse, numerical model was used to predict reaction rates and their depth distribution using Equation 3 by solving for  $R_x$  for data collected at Site 995 (for model parameters see Table 1). Cubic spline functions were used to fit methane concentration data providing the necessary gradient information used to calculate the first and second derivative terms of Equation 3. Cubic splines are particularly good for fitting purposes because they: (1) have no inherent functional form (e.g., like exponential or polynomial functions); (2) have continuous first and second derivatives; and (3) can be modified to accept measurement uncertainties (Ahlberg et al., 1967; Alperin, 1988; Alperin et al., 1988). Porosity data (Paull, Matsumoto, Wallace, et al., 1996) were fit using an exponential function that provided  $\phi_x$  and  $\phi_{\infty}$ . The free-solution coefficient ( $D_0$ ) used for methane was  $7.9 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$  (3°C; calculated from empirical data given by Li and Gregory, 1974; Lerman, 1979), based on a sediment temperature of ~4°C (Ruppel, 1997). The sedimentation rate was assumed to be constant at  $0.0057 \text{ cm y}^{-1}$  ( $5.7 \text{ cm ky}^{-1}$ ), based on the last appearance of *Pseudoemiliania lacunosa* (Paull, Matsumoto, Wallace, et al., 1996), which occurred at 0.46 Ma (Thierstein et al., 1977).

## RESULTS

### Sulfate Gradients

Sulfate gradients at Sites 994, 995, and 997 are linear through most of the sulfate reduction zone (Site 994, Fig. 2A; Site 995, Fig. 2B; Site 997, not shown, see Paull, Matsumoto, Wallace et al., 1996; Table 2). Sulfate gradients calculated by least-square linear regression are 1.41, 1.30, and 1.23  $\text{mM m}^{-1}$  respectively for the three sites; the sulfate-methane interface lies at 20.5, 21.0, and 22.7 mbsf. The sulfate gradient in piston core (PC) 11-8 is 2.88  $\text{mM m}^{-1}$  with a SMI depth of 10.3 mbsf (Fig. 2C).

Table 1. Model conditions and parameters for the finite difference, diffusion-advection-reaction model used to estimate methane reaction rates.

Parameter	Value	Source
$\phi$	$0.266 \times \exp(-0.0000235 \times x) + 0.459$	Exponential fit to measured porosity data (Paull, Matsumoto, Wallace, et al., 1996)
$\phi_{\infty}$	0.459	Fit to porosity data
$\omega$	$5.7 \text{ cm ky}^{-1}$	Last appearance, <i>Pseudoemiliania lacunosa</i> (Paull, Matsumoto, Wallace, et al., 1996)
$D_0 - \text{CH}_4$	$7.9 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$	3°C (Li and Gregory, 1974; Lerman, 1979)

Note:  $x$  = sediment depth (cm).

**Table 2. Interstitial water data for samples shallower than 60 mbsf, Sites 994, 995, and 997, and piston core 11–8.**

Notes: Complete concentration data for Sites 994, 995, and 997 in Paull, Matsumoto, Wallace, et al., (1996). mM = millimoles per liter or millimolar. PDB = Pee Dee belemnite carbon standard. CDT = Canyon Diablo Troilite sulfur standard. — = not measured.

## Methane

Methane concentrations (Table 3) are low through the sulfate reduction zone and then increase rapidly once low (<1 mM) pore-water sulfate concentrations occur (Fig. 2). These data are consistent with the placement of the sulfate-methane interfaces as shown at sites 994, 995, and PC 11–8. Methane concentration data from sites 994 and PC 11–8 are much noisier relative to that of Site 995 because of the crude headspace methods used. The methane data from Site 995 shown in Fig. 2B were obtained from measurements of methane concentration in two subcores, and these duplicate measurements deviate by <5% (Hoehler et al., Chap. 8, this volume).

## Interstitial $\Sigma\text{CO}_2$ and Alkalinity

The  $\Sigma\text{CO}_2$  concentrations increase monotonically as sulfate concentrations decrease (Table 2; Fig. 2). Within the sulfate reduction zone of PC 11–8,  $\Sigma\text{CO}_2$  concentrations are generally linear, but concave-down curvature occurs in the profiles near the sulfate-methane interface. The  $\Sigma\text{CO}_2$  concentrations show little variation immediately below the interface.

The  $\Sigma\text{CO}_2$  concentration data for ODP Sites 994 and 995 are stratigraphically sparse near the sulfate-methane interface (Table 2), so we have also included alkalinity values. Because  $\Sigma\text{CO}_2$  is the predominant control on alkalinity in this system (Fig. 2), the shape of alkalinity profiles mimics  $\Sigma\text{CO}_2$  profiles, with alkalinity also increasing with increasing sulfate consumption downcore. The values are linear in the upper sulfate reduction zone, but alkalinity shows an inflection point near the SMI, where alkalinity is higher than expected based on linear extrapolation from above. Alkalinity values show little variation for about 10 m below the interface, but begin to increase below 30 mbsf (Paull, Matsumoto, Wallace et al., 1996).

## $\delta^{13}\text{C}-\Sigma\text{CO}_2$

The carbon isotopic composition of dissolved  $\text{CO}_2$  of the overlying seawater is near 0 per mil (‰, PDB), but decreases rapidly within interstitial waters of the sulfate reduction zone (Sites 994 and 995, Fig. 2B, C; Table 2). Maximum enrichments of light carbon ( $^{12}\text{C}$ ) occur at the sulfate-methane interface, where  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  values are  $-37.3\text{‰}$  and  $-37.7\text{‰}$ , respectively for sites 994 and 995. Further downcore, light carbon composes less of the  $\Sigma\text{CO}_2$  pool. No  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  values are available for PC 11–8. At Site 995,  $\delta^{13}\text{C}$  values more depleted in  $^{13}\text{C}$  than  $-30\text{‰}$  lie between 13 and 24 mbsf.

## $\delta^{34}\text{S}-\text{SO}_4$

The sulfur isotopic composition of interstitial sulfate changes progressively downcore as sulfate is depleted (Table 2; Fig. 2). Sulfur in modern seawater sulfate has a  $\delta^{34}\text{S}$  value of  $+20.0\text{‰} \pm 0.1\text{‰}$ , CDT (Rees et al., 1978), and each site shows that interstitial sulfate becomes progressively enriched in heavy sulfur ( $^{34}\text{S}$ ) with increasing depth into the sulfate reduction zone. The fractionation observed in sulfate of PC 11–8 is significantly less than that at Sites 994 and 995, with the respective maximum  $\delta^{34}\text{S}$  values of  $+29.1\text{‰}$ ,  $+49.6\text{‰}$ , and  $+51.6\text{‰}$ .

## CALCULATIONS AND MODEL RESULTS

### Sulfate Flux

The flux of sulfate into the sediment from overlying seawater can be approximated from linear sulfate gradients using Fick's First Law:

$$J = D_0 \phi \frac{\partial C}{\partial x}, \quad (4)$$

where  $J$  is the flux,  $D_0$  is free-solution diffusion coefficient,  $\phi$  is porosity, and  $\partial C/\partial x$  is the concentration gradient (e.g., Lerman, 1979). Given a mean sediment porosity of 70% for the sulfate reduction zone (Paull, Matsumoto, Wallace, et al., 1996), sediment temperatures of  $\sim 4^\circ\text{C}$  (Ruppel, 1997), and a sulfate diffusion coefficient of  $5.8 \times 10^{-6} \text{ cm s}^{-1}$  ( $5^\circ\text{C}$ , Li and Gregory, 1974), the sulfate gradients from Sites 994, 995, and PC 11–8 predict sulfate fluxes of  $(8.8, 8.2, \text{ and } 18) \times 10^{-4} \text{ mmol cm}^{-2} \text{ yr}^{-1}$ , respectively.

### Mixing Model Results

An established approach of assessing the importance of AMO is to algebraically account for the carbon isotopic contributions of each component comprising the  $\Sigma\text{CO}_2$  pool (Blair and Aller, 1995). The  $\Sigma\text{CO}_2$  sources at the sulfate-methane interface include that from overlying seawater trapped within sediments during burial (sw), that derived from sedimentary organic matter during remineralization (om), and that produced by anaerobic methane oxidation (amo). In a closed system, the carbon isotopic composition of the pool at the SMI is related to its components by:

$$\delta^{13}\text{C}_{\text{total pool}} = (X_{\text{sw}})(\delta^{13}\text{C}_{\text{sw}}) + (X_{\text{om}})(\delta^{13}\text{C}_{\text{om}}) + (X_{\text{amo}})(\delta^{13}\text{C}_{\text{amo}}), \quad (5)$$

where  $X$  is the constituent's fraction of the total  $\Sigma\text{CO}_2$  pool,  $\delta^{13}\text{C}$  is the carbon isotopic composition, and the subscripts sw, om, and amo refer to  $\text{CO}_2$  donated from the sources listed above. For Site 995, the value of  $X_{\text{sw}}$  is fixed at 0.139 (seawater  $\Sigma\text{CO}_2$  concentration divided by  $\Sigma\text{CO}_2$  concentration at the SMI, or 2.3 mM/ 16.5 mM) with  $\delta^{13}\text{C}_{\text{sw}}$  equal to 0‰. The isotopic value of sedimentary organic matter at the Blake Ridge averages  $-21\text{‰} \pm 3\text{‰}$  PDB ( $N=120$ ; Brooks et al., 1983; Olsen, 1997), and this value is used for  $\delta^{13}\text{C}_{\text{om}}$ . The isotopic composition of methane at the interface is  $-101\text{‰}$  PDB (Hoehler et al., Chap. 8, this volume), and this value is used for  $\delta^{13}\text{C}_{\text{amo}}$  (assuming no fractionation during AMO). The proportions of  $C_{\text{om}}$  and  $C_{\text{amo}}$  composing the remaining fraction of the  $\Sigma\text{CO}_2$  pool ( $1.0 - 0.139 = 0.861$ ) are varied to produce the mixing line in Figure 4.

The mixing model estimates that  $\sim 24\%$  of the carbon within the  $\text{CO}_2$  pool at the sulfate-methane interface is derived from methane (Fig. 4). This is only a crude estimate because the system is open (i.e.,  $\text{CO}_2$  diffusion occurs), because carbonate mineral precipitation occurs (Rodriguez et al., Chap. 30, this volume), and because carbon fractionation occurs during AMO.

### Diagenetic Model Results

Modeling of methane concentrations provides an independent estimate of the amount of sulfate consumed by AMO. Although in situ methane concentrations of deep-water sediments are difficult to measure accurately (Paull et al., unpubl. data), methane concentrations less than the methane bubble saturation at surface temperature and pressure should reflect in situ concentrations because loss of methane through outgassing is unlikely. Hence, the methane concentration data (Table 3) are apparently suitable for modeling.

The method assumes steady state conditions so that the distribution and magnitude of reaction rates can be solved for by fitting observed concentration data and solving the diagenetic equation (Eq. 3) for  $R_x$  using numerical methods. A cubic spline fit to the methane concentrations measured in Site 995 sediments (Hoehler et al., Chap. 8, this volume) approximates these data well (Fig. 5A). The measured methane profile has inflections (see arrows Fig. 5A), accurately reflected in the cubic spline fit, that produce variations in the first and second derivatives. The model results identify the depths where methane consumption and methane production are expected, and indicates the magnitude of the reaction rates as a function of depth (Fig. 5B). Model results also show that methane consumption occurs over a 2-m interval ( $\sim 20.5\text{--}22.5$  mbsf), and that methane production oc-

curs immediately below (Fig. 5B). The modeled AMO reaction rates show peak values approaching  $5 \mu\text{M yr}^{-1}$  ( $0.005 \mu\text{mol cm}^{-3} \text{ yr}^{-1}$ ) just below 21 mbsf.

The integrated methane flux corresponds to the area under the first derivative of the cubic spline fit (not shown). The model predicts a total upward methane flux of  $2.9 \times 10^{-4} \text{ mmol cm}^{-2} \text{ yr}^{-1}$ . At Site 995, the corresponding total sulfate flux, calculated using Fick's First Law, is  $8.2 \times 10^{-4} \text{ mmol cm}^{-2} \text{ yr}^{-1}$ . Thus, approximately 35% of the total sulfate flux into the sediment is used to consume upwardly diffusing methane.

Model results from fitting the methane concentration values agree well with concentration and isotopic data. As expected, the slight inflection in the concentration trend within the methanogenic zone (Fig. 5A) causes the model to predict a shift from methane production to methane consumption, and the large inflection in methane concentration at the SMI coincides with peak methane oxidation rates. Furthermore, minimum  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  values are coincident with peak methane oxidation rates.

## DISCUSSION

### Evidence for Anaerobic Methane Oxidation

Together with a strongly concave-up methane profile (Martens and Berner, 1974), several additional lines of evidence indicate that sulfate and methane co-consumption occurs at the sulfate-methane interface: (1)  $\Sigma\text{CO}_2$  and alkalinity profiles indicate localized  $\text{CO}_2$  production there; (2)  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  values are extremely depleted in  $^{13}\text{C}$ , and are lowest within the logical depth-zone for AMO; and (3) sulfate gradients are linear throughout the sulfate-reduction zone.

The magnitude and position of isotopic values of  $\Sigma\text{CO}_2$  provide the most compelling evidence for AMO (e.g., Reeburgh, 1980). The  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  values more negative than  $-30\text{‰}$  PDB most likely indicate derivation from methane because the isotopic carbon composition of marine phytoplankton is generally heavier than  $-30\text{‰}$  (Deines, 1980). In addition,  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  values reach their lightest ( $-37.7\text{‰}$ ) at the SMI, where  $\text{CO}_2$  production is indicated by deviation from linearity in the  $\Sigma\text{CO}_2$  and alkalinity profiles (Fig. 2). This local increase in  $\Sigma\text{CO}_2$  is consistent with production of  $^{12}\text{C}$ -rich  $\text{CO}_2$  through sulfate and methane co-consumption, and the diffusion of light  $\text{CO}_2$  away from the SMI. Near invariant alkalinity and  $\Sigma\text{CO}_2$  concentrations some meters below the SMI are consistent with a net sink for interstitial  $\text{CO}_2$  in the uppermost methanogenic zone due to carbonate mineral authigenesis (Rodriguez et al., 1997, and Chap. 30, this volume).

Assuming steady state conditions, linear sulfate gradients within the sulfate-reduction zone are circumstantial evidence for focused consumption of sulfate at the sulfate-methane interface by AMO. Linear profiles imply sulfate diffusion through the sulfate-reduction zone and consumption at the interface where sulfate and methane co-occur (Borowski et al., 1996).

Microbial consumption of sulfate to form interstitial dissolved sulfide ( $\Sigma\text{HS}^-_{\text{dissolved}} = \text{S}^{2-} + \text{HS}^- + \text{H}_2\text{S}$ ) preferentially uses light ( $^{32}\text{S}$ ) sulfur by both sulfate reduction of SOM (Eq. 1) and AMO (Eq. 2). These fractionations create a dissolved sulfide pool depleted in heavy sulfur ( $^{34}\text{S}$ ; typically negative  $\delta^{34}\text{S}$  values), and create progressive enrichments of  $^{34}\text{S}$  in the residual sulfate pool ( $\delta^{34}\text{S}$  values more positive than  $+20\text{‰}$ ) (e.g., Chambers and Trudinger, 1979; Goldhaber and Kaplan, 1974). Although the sulfur isotopic composition of interstitial sulfate indicates microbial fractionation at all sites (11–8, 994, 995; Fig. 2), either or both sulfate-depleting mechanisms could qualitatively account for the observed  $\delta^{34}\text{S}_{\text{SO}_4}$  profiles.

### Intensity of AMO

The intensity of anaerobic methane oxidation operating at the sulfate-methane interface can be gauged by appraising how much methane carbon resides in the  $\Sigma\text{CO}_2$  pool, or by estimating the pro-

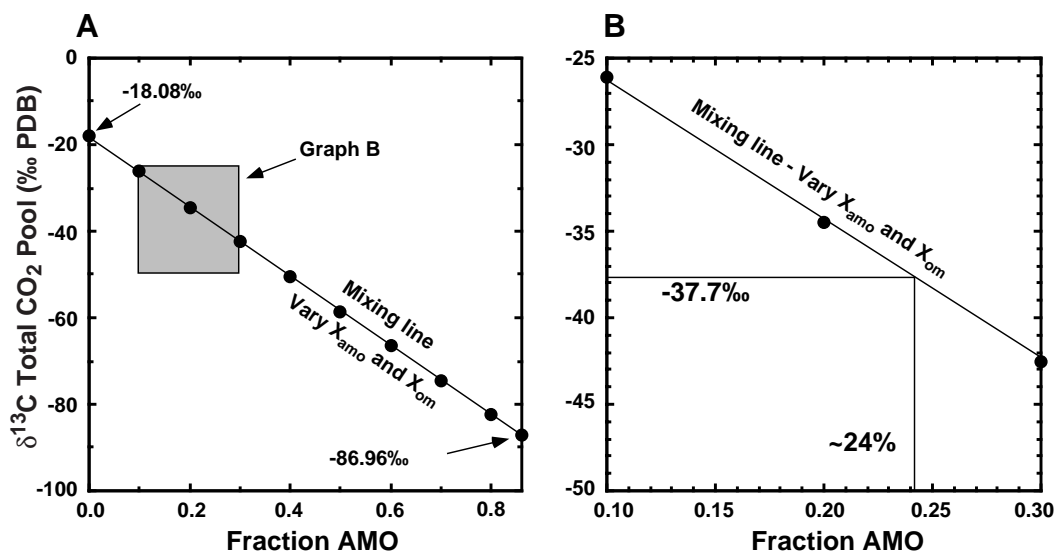

Figure 4. **A.** Diagram showing how varying amounts of carbon derived from methane via anaerobic methane oxidation (Fraction AMO) affect the carbon isotopic composition of the  $\Sigma\text{CO}_2$  pool ( $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$ ). **B.** An enlargement of the shaded box in **A**. The measured carbon isotopic composition of the  $\Sigma\text{CO}_2$  pool at the sulfate-methane interface at Site 995 is  $-37.7\text{‰}$ . Using this value, the model predicts that the  $\Sigma\text{CO}_2$  pool has received  $\sim 24\%$  of its carbon from methane, presumably through AMO.

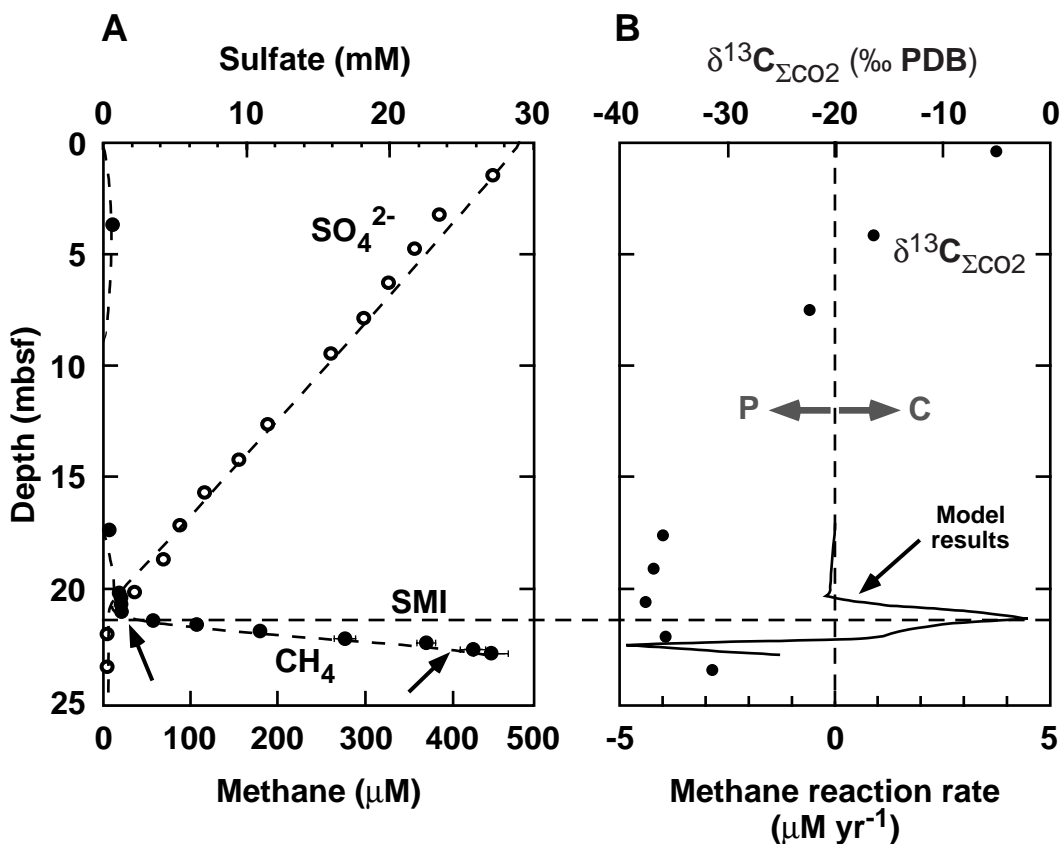

Figure 5. Graphs showing model results for Site 995 data. **A.** Sulfate concentrations (Paull, Matsumoto, Wallace, et al., 1996) and methane concentrations (Hoeherl et al., Chap. 8, this volume) measured at Site 995. A cubic spline function was used to fit the methane concentration profile. Inflections in the methane concentration trend are highlighted with arrows. The dashed line associated with sulfate concentrations is not a linear regression fit to the data like that in Figure 2B, but was calculated by the numerical model by increasing methane oxidation rates seen in Figure 2B by approximately three times. **B.** Zones for methane production (P) and consumption (C) predicted by the model, and calculated methane reaction rates (R) are in units of  $\text{mM yr}^{-1}$  (or  $\text{mmol cm}^{-3} \text{yr}^{-1}$ ).  $\delta^{13}\text{C}$  values of the dissolved  $\text{CO}_2$  ( $\Sigma\text{CO}_2$ ) pool are plotted for comparison.

portion of sulfate that AMO consumes relative to total sulfate flux into the sediments. Thus, we assess the importance of AMO at Site 995 using two independent methods: (1) a simple mixing model that considers the sources of  $\Sigma\text{CO}_2$  carbon (Eq. 5); and (2) a diagenetic model that utilizes the interstitial methane concentration profile to estimate methane consumption at the SMI (Eq. 3).

### Mixing Model

The  $\Sigma\text{CO}_2$  mixing model suggests that 24% of the carbon within the  $\Sigma\text{CO}_2$  pool has come from methane, but there are biases that affect this calculation. The largest potential bias is the diffusion of  $^{12}\text{C}$ -rich  $\text{CO}_2$  away from the sulfate-methane interface as suggested by the  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  profiles (Fig. 2). Such diffusive processes would act to lower the quantity of light carbon within the  $\Sigma\text{CO}_2$  pool and to lower the estimate of methane carbon.

Alternatively, carbonate mineral formation and the assumption of no carbon fractionation during AMO result in an overestimation of methane carbon within the  $\text{CO}_2$  pool. Fractionation during AMO allows entry of more  $^{12}\text{C}$  into the  $\text{CO}_2$  pool, but from a smaller proportion of methane. Thus, the model calculation overestimates the quantity of methane carbon in the  $\Sigma\text{CO}_2$  pool, however, an isotopic fractionation factor for AMO of 1.002–1.014 (Whiticar and Faber, 1986; Alperin et al., 1988) changes the calculation by only a few percent.

Carbonate mineral formation occurs within the zone of AMO (Rodriguez et al., Chap. 30, this volume), affecting  $\Sigma\text{CO}_2$  concentration. Large losses of  $\text{CO}_2$  only slightly affect the isotopic mass balance by changing the proportion of  $\text{CO}_2$  derived from seawater ( $X_{\text{sw}}$ ), and therefore altering the mix of  $\text{CO}_2$  carbon derived from organic matter ( $X_{\text{om}}$ ) and methane ( $X_{\text{amo}}$ ). Thus, the major effect of an open system on the model calculation lies not in the change of  $\text{CO}_2$  concentration, but in its effect on the isotopic composition of the  $\text{CO}_2$  pool. Accordingly, because the carbon fractionation involved in carbonate mineral formation is small (e.g., Emrich et al., 1970; Anderson and Arthur, 1983), the isotopic balance calculation is unaffected by this process.

The above factors interact to slightly vary the results of the mixing model, but the largest bias—diffusion of  $^{12}\text{C}$ -rich  $\text{CO}_2$ —acts to underestimate the contribution of methane carbon to the  $\text{CO}_2$  pool. The mixing model is relatively insensitive to  $\Sigma\text{CO}_2$  concentration and the AMO fractionation factor, cumulatively changing the estimate of the fraction of methane carbon to between 19% and 24%. A comprehensive interpretation is that at least one-fifth to one-fourth of the carbon within the  $\text{CO}_2$  pool is derived from methane through AMO.

### Diagenetic Model

The diagenetic model based on methane concentrations does consider diffusive processes and is unaffected by fractionations inherent in microbially mediated reactions because it contains no isotopic inputs. Thus, it is potentially a better tool in assessing the intensity of AMO. Based on methane concentration values, the model predicts that 35% of the total sulfate flux is consumed by AMO, but this may be an underestimate.

The linear sulfate profile of PC 11–8 (Fig. 2C) was reproduced by a finite difference diagenetic model that consumed 95% of the calculated sulfate flux through AMO (Borowski et al., 1996; Borowski, 1998). Increasing contributions of sulfate depleted by oxidation of SOM (Eq. 1), cause increasing curvature in the model results and increasing deviation from the observed sulfate concentration values. A similar predominant proportion of sulfate depletion due to AMO is necessary to approximate the sulfate data at Site 995 (see fit to sulfate data in Fig. 2A). The conundrum is that the model results based on methane data predict a much smaller proportion of sulfate consumed by AMO than do model results based on sulfate concentrations, although each model is internally consistent.

To adjust model results based on methane data to predict higher amounts of sulfate depletion due to AMO, in situ methane concentrations would have to be significantly higher than measured values. Methane loss may occur through outgassing, diffusion, and consumption by aerobic or anaerobic methane oxidation. However, the coincidence of modeled peak methane oxidation rates with the most  $^{13}\text{C}$ -depleted  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  values suggest that the measured methane concentrations faithfully reproduce at least relative changes in methane concentration.

To adjust sulfate data to reflect lower amounts of sulfate depletion due to AMO, in situ sulfate concentrations must be lower than measured concentrations, or sulfate must be renewed in situ. There are three known mechanisms that could add additional sulfate: (1) oxidation of interstitial dissolved sulfide during sediment and pore-water processing (e.g., Almgren and Hagstrom, 1974); (2) oxidation of sulfide minerals during processing; or (3) in situ anaerobic oxidation of dissolved sulfide by manganese and/or iron oxide minerals (Sorensen and Jorgensen, 1987; Aller and Rude, 1988; Fossing and Jorgensen, 1990; Elsgaard and Jorgensen, 1992; Schulz et al., 1994).

However, sulfide concentration and sulfur isotopic data show no obvious indication that these processes occur in Blake Ridge sediments:

- a. Typical interstitial dissolved sulfide concentrations in Blake Ridge pore waters are usually  $<10\ \mu\text{M}$  and almost always less than  $120\ \mu\text{M}$  (except at methane seep sites, Paull et al., 1995; Borowski, 1998). Thus, only a very small amount of oxidized sulfide could be added to the sulfate pool as an artifact of sampling.
- b. Sulfide minerals in the sulfate reduction zone of Sites 994, 995, and 997 have a mean  $\delta^{34}\text{S}$  value of  $-38.8\text{‰} \pm 5.3\text{‰}$  ( $N = 30$ , Borowski, 1998). Pore-water  $\delta^{34}\text{S}_{\text{SO}_4}$  values consistently show  $^{34}\text{S}$  enrichment at all sites (Fig. 2), rather than showing any addition of light sulfur from light sulfide derived from oxidized sulfide minerals. Thus, the data do not indicate that the oxidation of very  $^{34}\text{S}$ -depleted sulfide minerals during core handling has occurred.
- c. To significantly alter sulfate concentration gradients, sizeable amounts of dissolved sulfide, derived from sulfate consumed by sulfate reduction processes, must be oxidized in situ. Because of the argument in (b), if this process occurs it is masked by sulfur disproportionation reactions (Canfield and Thamdrup, 1994). Although there is ample evidence for anoxic sulfide oxidation elsewhere (see references above), we cannot identify its effects in Blake Ridge sediments. Moreover, we infer that anoxic sulfide oxidation is most likely to occur preferentially within the uppermost portion of anoxic sediments (where iron and manganese oxides are readily available; e.g., Aller and Rude, 1988), not deep within the sulfate-reduction zone.

To summarize, we have confidence in our data, but have not resolved the inconsistencies between the different model results. Either there is some undiscovered defect in the models or model assumptions, or there are unrecognized processes that we cannot adequately account for, nor quantify. Future modeling attempts may resolve the issue, especially by testing how modified diagenetic models predict the magnitude and distribution of  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  and  $\delta^{13}\text{C}_{\text{CH}_4}$  values. Even with the inconsistencies between model results using methane versus sulfate data, a conservative interpretation is that 35% of the total sulfate flux is consumed by AMO at Site 995.

### Areal Variation

There is evidence for a still larger role for AMO, relative to the results at Site 995, at other sites of the CR-BR area. Fully 40% (17 of 42) of the nondiapir sites over the Carolina Rise and Blake Ridge

have sulfate gradients steeper than those observed at Site 995 (Borowski, 1998). If sulfate consumption through AMO induces linearity in the sulfate profiles, we infer that these sites may have a larger proportion of sulfate depleted via AMO versus sulfate reduction of SOM. For example, Site PC 11-8 (Fig. 2C) shows the largest amount of sulfate depletion recorded at nondiapir sites with a gradient of 2.88 mM m<sup>-1</sup> (vs. 1.30 mM m<sup>-1</sup> at Site 995), a SMI depth of 10.3 mbsf (vs. 21 mbsf at Site 995), and a predicted sulfate flux of  $18 \times 10^{-4}$  mmol cm<sup>-2</sup> yr<sup>-1</sup>, or 2.2 times that of Site 995 ( $8.2 \times 10^{-4}$  mmol cm<sup>-2</sup> yr<sup>-1</sup>).

### Implications

The indication that AMO is such a significant sink for interstitial sulfate in these deep-sea sediments is surprising. Large fractions of sulfate consumed by AMO have been documented elsewhere (Table 4), but only at seep or advective sites (not tabulated; e.g., Suess and Whiticar, 1989; Masuzawa, et al., 1992; Cragg et al., 1995; Paull et al., 1995) in organic-rich coastal marine environments (e.g., Saanich Inlet, see Table 4 for references), or in marine basins that have anoxic water columns such as the Black Sea (Reeburgh et al., 1991) and Cariaco Trench (Reeburgh, 1976). Unlike these anoxic basins, the overlying water of the CR-BR area is oxygenated, implying a different impetus for intensified AMO.

Borowski et al. (1996) suggested that the magnitude of upward methane flux controls the intensity of AMO occurring at the sulfate-methane interface, which in turn influences sulfate concentrations (and perhaps produces linear sulfate gradients). Pore-water data presented here, especially  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  data, firmly establish AMO as an important diagenetic process at Site 995. Although independent diagenetic modeling results are inconsistent, or do not fully explain the data, a model using methane concentrations (Site 995) suggests that 35% of the total sulfate flux is consumed by AMO. Such large proportions of AMO must affect sulfate concentration gradients. If such an enlarged role for AMO is indeed fueled by upward methane flux, we infer that similar interstitial chemistries should also occur at other continental rise, methane-rich, gas hydrate-associated settings. Thus, steep (and linear) sulfate gradients may be a geochemical indicator of methane-rich sediments, and may also be an indicator for the presence of gas hydrates in continental rise sediments, given that conditions are suitable for gas hydrate formation.

### CONCLUSIONS

1. A unique, high-resolution data set consisting of pore-water concentration and isotopic data was gathered through the sulfate-reduction zone and within the uppermost methanogenic zone of Sites 994, 995, and 997 (ODP Leg 164).

2. Linear sulfate gradients are common within the sediments of the Carolina Rise and Blake Ridge, occurring at widely distributed ODP and piston-core sites.

3. Concave-up methane profiles, linear sulfate gradients, patterns of interstitial dissolved CO<sub>2</sub> concentration, and extremely <sup>13</sup>C-depleted  $\delta^{13}\text{C}_{\Sigma\text{CO}_2}$  values consistently suggest that anaerobic methane oxidation is a significant sulfate-consuming process at all three ODP sites.

4. An inverse diagenetic model based on measured interstitial methane concentrations estimates that 35% of the total sulfate flux into the sediments at Site 995 is consumed by anaerobic methane oxidation.

5. Forty percent of the (nondiapir) sites sampled in the CR-BR area (by both piston coring and drilling operations) possess linear sulfate gradients larger than that seen at Site 995, implying that anaerobic methane oxidation may be responsible for even larger proportions of total sulfate depletion at these sites.

6. The wide occurrence of steep (linear) sulfate gradients over the Carolina Rise and Blake Ridge suggests that anaerobic methane oxidation is an important, additional process in consuming interstitial sulfate in these gas hydrate-associated sediments. Methane-rich sediments elsewhere, including those associated with gas hydrates, are expected to display similar chemistries.

**Date of initial receipt: 21 April 1998**

**Date of acceptance: 12 January 1999**

**Ms 164SR-214**

**Table 4. Table showing marine localities (coastal and deep-sea sediments) where anaerobic methane oxidation (AMO) is an important process.**

Location	Maximum AMO rate ( $\mu\text{mol cm}^{-3} \text{yr}^{-1}$ )	Method	Depth to SMI (mbsf)	Sulfate depletion due to AMO (%)	Lightest $\delta^{13}\text{C}\text{-}\Sigma\text{CO}_2$ (‰ PDB)	$\delta^{13}\text{C}$ -organic matter (‰ PDB)	Reference
<b>Coastal Marine:</b>							
Amazon Shelf (OST-2)	—	Model $\text{CH}_4$	0.60-0.67	—	-29 (at SMI)	-22	Blair and Aller (1995)
Cape Lookout Bight (Coastal North Carolina)	70-510	Labeled $\text{S}^*\text{O}_4$	—	—	—	—	Crill and Martens (1987)
	2.9	Labeled $\text{C}^*\text{H}_4$	0.05	—	-10 to -15 (at SMI)	—	Blair et al. (1993)
	4.4-5.5	Labeled $\text{C}^*\text{H}_4$	0.05-0.12	—	—	—	Alperin et al. (1992)
	—	—	—	—	-5 to -15 (at SMI)	-19.2 $\pm$ 0.2	Hoehler et al. (1994)
	—	—	—	—	—	—	Boehme et al. (1996)
Kysing Fjord, Denmark	0.017-0.102	Labeled $\text{C}^*\text{H}_4$	0.01-0.05	0.01-0.06	—	—	Iversen and Blackburn (1981)
Jutland and Kuttegat, Denmark	2.0-4.0	Labeled $\text{C}^*$	0.2-1.3	10-17	—	—	Iversen and Jorgensen (1985)
	2-6.6	Labeled $\text{S}^*\text{O}_4$	—	—	—	—	—
Long Island Sound	0.65	Model $\text{CH}_4$	0.15-0.80	—	—	—	Martens and Berner (1977)
Skan Bay, Alaska	1.8-3.4	Labeled $\text{C}^*$	0.18	5-20	-19 to -21 (at SMI)	-21	Reeburgh (1980)
	3.65	Labeled $\text{C}^*\text{H}_4$	—	—	—	—	Alperin and Reeburgh (1984)
	5-20	Labeled $\text{C}^*\text{H}_4$	—	—	—	—	Alperin et al. (1988)
	29	Labeled $\text{C}^*\text{H}_4$	—	—	—	—	Alperin et al. (1992)
Saanich Inlet, Vancouver	—	—	<0.15-0.30	—	—	-20 to -24	Brown et al. (1972)
	—	—	<0.10-0.85	—	-37.1 (near SMI)	—	Nissenbaum et al. (1972)
	—	Model $\text{SO}_4$	0.17-0.24	75	—	—	Murray et al. (1978)
	35-78	Labeled $\text{S}^*\text{O}_4$	0.17	30-70	—	—	Devol and Ahmed (1981)
	1.7-7	Labeled $\text{C}^*\text{H}_4$	—	—	—	—	Devol (1983)
	35-70	Labeled $\text{S}^*\text{O}_4$	—	—	—	—	—
	2.6-6.6	Labeled $\text{C}^*\text{H}_4$	0.12	23-40	—	—	Devol et al. (1984)
	17-52	Labeled $\text{S}^*\text{O}_4$	—	—	—	—	—
	30	Model $\text{CH}_4$	—	—	—	—	—
	30	Model $\text{SO}_4$	—	—	—	—	—
Santa Barbara Basin	0.232 (46 cm zone)	Model	0.90-2.1	—	—	—	Barnes and Goldberg (1976)
	0.128 (mean)	Labeled acetate	—	—	—	—	Kosior and Warford (1979)
<b>Deep Sea:</b>							
Black Sea (BS5-10)	$(4.6-9.5) \times 10^{-4}$	Labeled $\text{C}^*\text{H}_4$	Anoxic water column	—	—	—	Reeburgh et al. (1991)
	—	—	—	—	—	-22 to -27	Fry et al. (1991)
Cariaco Trench	0.55-1.59 (10 cm zone)	Model $\text{CH}_4$	0.55-0.70	50	—	—	Reeburgh (1976)
	—	—	—	—	—	-19 to -21	Fry et al. (1991)
Gulf of Mexico (DSDP Site 88)	—	—	5-54	—	-30 (4 mbsf)	—	Presley et al. (1973)
Blake Ridge (DSDP Site 533)	—	—	9.8-14.4	—	-31.4 (14 mbsf)	—	Claypool and Threlkeld (1983)
Blake Ridge (ODP Site 995)	0.005	Model $\text{CH}_4$	20	-33	-37.7 (20 mbsf)	-21 (mean)	This paper
Norwegian Sea (ODP Site 644)	—	—	6-22	—	-31.8 (22 mbsf)	—	Vuletic et al. (1989)
Sulu Basin (ODP Site 768)	—	—	~172	—	-34 (172 mbsf)	—	von Bryemann et al. (1991)
Nankai Trough (ODP Site 808)	—	—	3-13.8	—	-29.8 (3 mbsf)	—	Gamo et al. (1993)
	—	—	—	—	—	-23 to -25	Berner and Koch (1993)
Offshore Namibia	—	Flux calculation	3.5-10	40-100	—	—	Niewohner et al. (1998)

Note: \* = radioisotopes. SMI = Sulfate/methane interface, PDB = Pee Dee belemnite standard. — = not measured.
